“Let me put it another way. You have a computer with an auto-dial phone link. You put the VIRUS program into it and it starts dialing phone numbers at random until it connects to another computer with an auto-dial. The VIRUS program then *injects* itself into the new computer. Or rather, it reprograms the new computer with a VIRUS program of its own and erases itself from the first computer. The second machine then begins to dial phone numbers at random until it connects with a third machine....

- A file transfer mechanism (not quite email, though it could have been) delivered a short script to users
- It was written in REXX, a shell script-like language for IBM's VM/CMS system
- The script displayed the Christmas card; it also looked through the (equivalent of) the user's email alias file and the file transfer log
- It transmitted a copy of itself to any usernames it found
- People trusted it, because it was coming from a regular correspondent...

- The `finger` daemon call `gets()`, a now-deprecated library routine
- Unlike `fgets()`, there was no buffer length parameter
- By sending a long-enough string over the network as input, the attacking program
 1. Injected some assembler-language code, and
 2. Overwrote the return address in the stack frame so that `gets()` branched to that code instead of back to the caller

Buffer Overflows Shouldn't Happen!

“The first principle was security: ... A consequence of this principle is that every occurrence of every subscript of every subscripted variable was on every occasion checked at run time against both the upper and the lower declared bounds of the array. ... I note with fear and horror that even in 1980, language designers and users have not learned this lesson. In any respectable branch of engineering, failure to observe such elementary precautions would have long been against the law.”

Turing Award Lecture, C.A.R. Hoare

- Exploit trust patterns: `/etc/hosts.equiv` and per-user `.rhosts` files list trusted machines
- If machine A trusts machine B (if only for a particular user), machine B usually trusts machine A
- This provided two things: an infection path and a list of other machines to attack

- It looked at a variety of sources to find other machines to attack:
 - ◆ rsh/rlogin trust sources
 - ◆ Machines listed in `.forward` files
- Routers (in 1988, most routers were general-purpose computers)
- Randomly-generated addresses on neighboring nets

Hiding

- The worm used a variety of techniques to hide
- It was named `sh`
- It forked frequently, to change processID
- It unlinked its own executable
- Text strings were (lightly) encrypted

- Exploited a bug in Microsoft's SQL server
- Used UDP, not TCP — a single 376-byte packet to UDP port 1434 could infect a machine!
- Use of UDP instead of TCP let it spread much faster — one packet, from a forged source address, instead of a three-way handshake, payload transmission, and a three-packet `close()` sequence
- No direct damage, but it clogged network links very quickly

- How are worms detected?
- Initially, by honeypots and by people sending samples of suspicious code to anti-virus companies
- A/V companies build worm *signatures*
- Signatures are byte patterns that match that file
- Every new worm or worm variant needs its own signature, which is why anti-virus scanners need weekly updates
